The objective of this study is to report two cases of cancer patients suffering from osteoradionecrosis infection by understanding the risk factors for infection and knowledge about Actinomyces sp. The control of bone necrosis and risk of recurrent infections. The treatment is complicated due to insidious growth pattern of Actinomyces sp. The methods for diagnosis and therapeutic approaches constitute challenges that underscore the need for understanding the risk factors for infection and knowledge about clinical conditions associated with this pathology. The objective of this study is to report two cases of cancer patients suffering from an osteoradionecrosis infection by Actinomyces sp., to describe approaches and discuss therapeutic options in the light of the current literature.

KEYWORDS: Actinomycosis. Osteoradionecrosis. Osteonecrosis by bisphosphonates.

INTRODUCTION

Osteoradionecrosis (ORN) is a major complication resulting from oncological treatment for head and neck cancer (HNC) and can occur in the period of a few months to years after radiotherapy (HANSEN et al., 2006; HALL, 2008; KHOJASTEPOUR et al., 2012; TURNER et al., 2013). Its definition and etiology are still under discussion, but the radiotherapy appears to cause ORN because it affects the small blood vessels of bone, inducing inflammation (endarteritis), which favors the generation of small thrombi that obliterate the vascular lumen and thus interrupt tissue perfusion. Likewise, RT produces an increase in free radicals and alters collagen synthesis. The bone loses its normal cellularity and undergoes fibrosis-atrophy with impairment of its repair and remodeling capacity (CHRCANOVIC et al., 2010). Under such conditions even minimal external trauma causes ulceration, facilitating contamination and infection, and thus favoring bone necrosis (SILVESTRE-RANGIL et al., 2011; TURNER et al., 2013). The pathogenesis of ORN is related to induced trauma or spontaneous injury and / or infection, in the intra-oral mucosa, fistulas and pathologic fracture of the mandible. In advanced cases, surgery is generally necessary and in other situations, the disease may prove to be intractable. The incidence of ORN is estimated to be around 5% to 35%, and varies with the radiation dose, treatment time, and the general state of the patient (HANSEN et al., 2006; HALL, 2008; KHOJASTEPOUR et al., 2012).

Recently, new considerations about ORN and its relationship with infection have been described. The irradiation of the mandible during treatment of tumors in the head and neck region can lead, at a later date, bone damage and in the surrounding soft tissue (KHOJASTEPOUR et al., 2012), reduce the integrity of the oral mucosa, facilitating infection by Actinomyces sp (CHUNG et al., 1998). Infected osteoradionecrosis (IORN) is defined as necrosis of the bone after irradiation of the mandible with clinical signs of infection, and with exposure of bone necrosis, inflammatory infiltrates and fistula formation or bone sequestration (HANSEN et al., 2007). The IORN is typically associated with pathogens such as Candida sp. and cariogenic bacteria of the genus Actinomyces (HANSEN et al., 2006; ANDREWS and GRIFFITHS, 2001).

Mandibular actinomycosis is a rare disease, which has been recently described in patients with IORN (HANSEN et al., 2007; ABIR et al., 2013). It is a suppurating, chronic, granulomatous and
fibrosing disease. It is a relevant condition due to its aggressive and locally destructive nature (RUSSO, 2010; SMITH et al., 2011; ABIR et al., 2013). After the initial infection, the spread of bacteria in the body occurs by direct invasion of tissues, usually fibrotic and relatively avascularized. The main species are *A. israelli* and *A. gerencseriae* (HALL, 2008; FINLEY and BEESON, 2010; ABIR et al., 2013). The infectious process is generally slow with growth of the mass occurring over time. A more rare presentation is an acute abscess which grows rapidly causing pain and trismus (HANSEN et al., 2007; FINLEY and BEESON, 2010).

Colonies of *Actinomyces* have a very typical morphology in microscopic slides and are thus fairly easy to identify. They tend to create a mass of filamentous bacteria, with variations in the color between the center and periphery of the colony (the so called “sun-ray” effect). PAS, Gram, and silver stains are typically positive (NEVILLE et al., 2002; GOLDBERG et al., 2003). In contrast to the ease of microscopic identification, the clinical significance of finding colonies compatible with *Actinomyces* in biopsy specimens is often unclear, affecting treatment planning in these cases (KAPLAN et al., 2009). Infection by *Actinomyces* has also been suggested to be responsible for deterioration in outcome in cases of osteoradionecrosis of the jaws. (HANSEN et al., 2006; KAPLAN et al., 2009)

The objective of this study was reported two cases of cancer patients suffering from an osteoradionecrosis infection by *Actinomyces sp*, to describe approaches and discuss therapeutic options in the light of the current literature.

**Case Reports**

**Case 1**

Patient male, 42 years old, ex-smoker and social drinker. The patient had the diagnosis of nasopharynx squamous cell carcinoma in 2005, staging T2N2M0. Patient was submitted to chemoradiation treatment (Intergroup Protocol 0099 - cisplatin 100mg/m2 D1, 22,43 concomitant with radiotherapy - total dose of radiotherapy performed with linear accelerator of 6 mV: 7200 cGys followed by 3 cycles adjuvant chemotherapy with cisplatin (D1) associated with fluorouracil for 96 hours. In 2008 the patient evolved with pain in the right mandibular region and was referred to the Department of Dentistry of the Association Against Cancer of Center West of Minas Gerais/Brazil. He reported a history of a tooth extraction in the affected region in the previous year. On intraoral examination, the patient presented an ulcerated region with exposure of necrotic bone and purulent collection in the body of the mandible. Radiographically a area with diffuse limits was observed (Figure 1 A).

![Figure 1. In case 1, panoramic radiography showing the evolution (A, C e D) of the osteonecrosis in infected jaws by *Actinomyces sp* colony (B) with bony sequestrate (→). Observe the presence of *Actinomyces sp* colony (*) and bone necrosis (arrowhead) in micrograph.](image)
A biopsy confirmed the diagnosis of ORN and mandibular infection colonized by *Actinomyces* sp. Microscopy revealed the presence of inflammatory infiltrate with a predominance of lymphocytes and plasma cells, and numerous *Actinomyces* sp colonies in the intertrabecular tissue (Figure 1 B). The fragments of the oral mucosa showed cellular reactive changes in the squamous epithelium. The patient underwent surgery for bone debridement to remove bone sequestration, and was referred to the treatment with long-term antibiotics (ampicillin – every 6 hours). In 2010 patient evolved with neck recurrence and was submitted right neck lymphadenectomy. In 2011, the patient evolved with recurrence of osteonecrosis developed a pathological fracture in the mandibular ramus (figure 1 C). The patient was submitted to a noninvasive treatment, (sequestrectomy, and extraction of affected tooth - second bicuspid) and long term antibiotics. He is currently asymptomatic and without IORN recurrence in radiography (figure 1D).

**Case 2**

Patient female, 76 years of age, nonsmoker, non-drinker. In 2006, she was diagnosed with squamous cell carcinoma of the tongue, stage T2N1M0. She underwent surgery (partial glossectomy and radical neck dissection) and radiotherapy treatment with linear accelerator of 6 mV (total dose: 6120 cGys).

In 2007, the patient developed pain in the right mandible and radiographic findings revealed a radiolucent lesion (figure 2 A-B).

The intraoral examination showed ta fistula of the right gingival ridge. Imaging studies showed osteolytic areas of the bone. In order to relieve his symptoms and reach a diagnosis, debridement of the infected area (including removal of the bony sequestra) was undertaken and the tissue was sent for histological examination. The histopathological examination confirmed an infection with

actinomycosis associated with osteoradionecrosis. The patient underwent treatment with long-term antibiotics (ampicillin – every 6 hours) and observe satisfactory local control of disease for ten months. In subsequent years (2008 and 2009) new biopsies were performed that revealed recurrences of actinomycosis infection. In March 2011, the intraoral examination revealed progression of bone necrosis with periodontal bone involvement, of some dental elements. The bone debridement and extractions of affected teeth were performed. Histopathological analysis of the bone fragments revealed persistent infection by *Actinomyces* sp. Antibiotic therapy was reinitiated and the patient is systematic monitoring of the multidisciplinary team (head and neck surgeon, infectious disease specialist, and dentist). The patient is currently alive without tumor recurrence. Nevertheless she lost gradually the alveolar bone due to osteoradionecrosis and thereafter the lower teeth (figure C). We could not perform the prosthetic oral rehabilitation. The patient is unable to ingest solid food. Because of this complication, the patient has important functional and aesthetic limitation that interfere with quality of life.

**DISCUSSION**

The possible role of *A. israelii* in infected osteoradionecrosis (IORN) was described in 1983 (HAPPONEN et al., 1983). The authors reported five cases in which actinomycosis was confirmed by histopathologic examination with identification of *A. israelii*. However, in the same year, Marx (MARX, 1983) challenged the concept of infectious etiology of ORN and suggested that the microorganisms detected were only superficial contaminants.

Actinomycosis was again associated with infected osteoradionecrosis in 2000, when Curi et al. (2000) reported the diagnosis of 12% of 50 cases of mandibular osteoradionecrosis, based on histological evidence. The findings of this study demonstrated a significant increase in the time required for remission of ORN in cases of positive *Actinomyces*.

Bacteria *A. israelii* and *A. gerencseriae* are the main causative agents of actinomycosis associated with maxillary IORN, while *A. odontolyticus*, *A. meyeri*, *A. naeslundii* / *A. viscosus* and *Propionibacterium propionicum* are less frequently implicated (PULVERER et al., 2003).

More recently, Store et al., taking great care to eliminate surface contamination, examined 12 deep medullary specimens of resected mandibles by DNA–DNA hybridization. Using the checkerboard method with probes for *A. israelii*, *A. gerencseriae*, *A. viscosus* and 17 other oral organisms, multiple species including *A. viscosus* and/or *A. gerencseriae* were detected in all of 12 samples. In this same work, multiple species, including *A. viscosus* and/or *A. gerencseriae* were detected in the 11 samples (STORE, ERIBE and OLSEN, 2005).

The study by Hansen et al. (2006) histological evidence of actinomycosis was found in 29 of 31 cases of IORN at a frequency of 64.5% (HANSEN et al., 2006). Sulfur granules were seen almost exclusively in areas of bone necrosis, suggesting a true infection, rather than surface contamination postulated by some authors. They concluded that actinomycosis occurs more frequently (64.5%) in ORN than previously thought. Furthermore, they demonstrated that 38.1% of the patients developed IORN after extraction of teeth, proving the common knowledge that dental extractions are associated with the risk of developing IORN. This study confirms previous findings by Curi et al. (2000) which suggested that an *Actinomyces* positive bone biopsy indicated a worsened prognosis.

Another study by Hansen et al. (2006) investigated patients diagnosed with actinomycosis, with special attention paid to the underlying disease. Forty-five patients were included in the study and 43 presented a diagnosis of osteonecrosis with bisphosphonates (58.7%) and IORN (35.6%). Only three patients (6.7%) presented without a history of cancer treatment. In all cases, they found a direct association between Actinomyces colonies and bone in the space surrounding the bone marrow. Inflammatory infiltrates with varying amounts of osteoclasts were a typical finding. Furthermore, pseudoepitheliomatous hyperplasia occurred in 60.9% of patients.

This study reported cases of patients undergoing oncological treatment who developed late complications related to cervicofacial radiotherapy. The cancer treatment conferred the locoregional control of the disease and these patients completed six years of disease-free survival. However, complications arising from treatment interfered negatively on quality of life of these patients. The etiology of the first case reported probably occurred through contamination of the socket after tooth extraction in a patient with a history of cervicofacial irradiation and compromised healing. The second case showed no correlation to ORN with an identifiable precipitating factor. The therapeutic conduct instituted consisted of treatment with oral antibiotics for a prolonged period, and
surgical approach for bone debridement, in order to prevent recurrence. In both cases, there were difficulties in controlling the disease site, and frequent recurrences of infection and progression of bone necrosis. The clinical findings and therapeutic results of this study confirmed previous studies that described a poor prognosis for patients affected by IORN from Actinomyces sp (HANSEN et al., 2006; HANSEN et al., 2007; VAN HALL, 2007; KAPLAN I et al., 2009).

Therefore, according to the findings the presence of Actinomyces sp in histological findings constitutes a poor prognostic factor, and treatment-related sequelae affect quality of life and increase the costs of care.

**CONCLUSION**

Osteoradionecrosis is a major challenge with regard to therapeutic conduct and patient rehabilitation. The presence of Actinomyces sp is a poor prognostic factor related to the control of the disease, causes significant morbidity and, consequently, a considerable impact on quality of life of the patient. Understanding the risk factors related to the pathogenesis becomes imperative for the development of protocols for the prevention and management of this disease.
