METABOLIC EFFECTS OF EARLY PROTEIN UNDERNOURISHMENT AND RENOURISHMENT IN WISTAR RATS

EFEITOS METABÓLICOS DA SUBNUTRIÇÃO PROTEICA PRÉ-NATAL E RENUTRIÇÃO EM RATOS WISTAR

ABSTRACT: Malnutrition remains an important public health condition by affecting mostly children. The present study aimed to examine the effects of prenatal protein undernutrishment and postnatal renourishment on the metabolism of pre-adult animals. Forty-five male Wistar rats originating from different litters were used. The Nourished (N, n=15) and Undernourished (U, n=30) groups were maintained on proteic and hypoproteic diets (20% and 5% casein, respectively) from the intrauterine phase until the end of the experiment. The Renourished group (R) contained 15 animals, randomly chosen from U group, that consumed the N diet beginning on day 21 (weaning). All groups were maintained until day 60. The experimental data was acquired daily for body weight, feed and water intake, feces and urine excretion. Data analysis was made with the total results and the ratio between them. The U group animals developed uniformly sparse hair late and experienced intense sweating, features that were not observed during the experiment in the R and N animals groups. The R group had the largest weight gain and feed and water intake ratio/weight at experimental period, followed by the N group animals. The final body weight and food intake decreased gradually in the order N-R-U, but none of the other parameters showed a statistical difference between the N and R animals. Compared to groups N and R, the U group animals consumed 90% and 81% more food and water, respectively. Protein undernourishment induced metabolic dysfunction in the U group animals. The similarity in the experimental parameters of the N and R groups suggests that an early feeding correction was effective in reestablishing the organic functions of the R group animals.

INTRODUCTION

Undernourishment is caused by an improper diet, either hypocaloric (marasmus) or hypoproteic (kwashiorkor), and can be determined by the poor absorption of nutrients or anorexia. This condition has been the focus of several studies since the early seventies, including those that used experimental models(ANTHONY; EDOZIEN, 1975), since it is one of the most important public health problems worldwide. It affects mainly the most susceptible age groups, such as infants and children, during critical developmental periods(MONTE, 2000).

The number of undernourished children in the world today surpasses 500 million. Moreover, more than half of the deaths in this population group are attributed to undernourishment. The other major causes of death are malaria, acute respiratory infections, diarrhea, tuberculosis and HIV/AIDS; however, these are often complicated by, or have a direct connection to, different degrees of undernourishment(NEUMANN; GEWA; BWIBO, 2004).

Due to the magnitude and the disastrous consequences on growth, development and survival, child undernourishment remains a major public health problem in the world today(MONTE, 2000). The delay in growth and development makes the body more susceptible to immune system deficiencies, infections and neuropsychomotor problems, as well as morphological, behavioral and cognitive changes(NUNES et al., 2002). The effect on growth, in particular, is a major focus of attention in children's health, with the anthropometric delay being a major factor in the epidemiological malnutrition data from Brazil and the world(ROMANI; LIRA, 2004; WATERLOW, 1997).

Several studies have been published on the effects of protein undernourishment and the role the renourishment plays in various organs and tissues(BAPTISTA JS et al., 2013; GREGGIO et al., 2010; LIBERTI et al., 2007; OLIVEIRA et al., 2010). However, the morphological and structural changes caused by this state of protein deprivation did not reveal or bring understanding to the
Metabolic effects of early protein undernourishment in rats—systemic metabolic consequences and experimental protocol

MATERIAL AND METHODS

Animals and experimental groups

The present study was approved by the Ethics Committee on Animal Experimentation (CEEA, University of São Paulo-USP, number 31, sheet 44, book 2). The experimental protocol was performed with adaptations from previously published work by our group (GREGGIO et al., 2010; LIBERTI et al., 2007; OLIVEIRA et al., 2010). Wistar rats (Rattus norvegicus) were used (23 males and 23 females, between 90 and 120 d of age with body masses between 280 and 320 g), obtained from the animal colony of the Biomedical Science Institute, USP. These animals were mated for seven days in standard plastic cages in the vivarium of the Department of Anatomy, USP, in air-conditioned rooms with controlled temperature (23 to 25°C) and 12 h light/dark cycle. During the experimental period, the animals received water and food ad libitum: proteic (20% casein) for the nourished group (N; n = 8 pairs), or hypoproteic (5% casein) for the undernourished group (U; n = 15 pairs). The diets were prepared by a specialized biochemical laboratory (Rhoster Industry and Trade LTD, Aracoiaba da Serra, SP, Brazil) according to the "American Institute of Nutrition" for the standardization of diets in laboratory animals (REEVES; NIELSEN; FAHEY, 1993).

After the confirmation of pregnancy, the females were separated into individual cages and continued to be fed their respective diets: N (8 females) and U (15 females). These animals were monitored daily for the birth of new litters. To standardize the experiment, only litters with six pups from both groups were used. The adoption of this criterion ensured a lower discrepancy in the body mass of the obtained animals and the same stress level between mothers of both groups. Thus, the only variable experimental factor for this protocol was the type of diet.

The mothers were maintained on their respective diets until their cubs completed 21 days of extrauterine life, which was the determined weaning time. Two males from each litter were randomly assigned for experimental standardization, and the animals that were not selected were excluded from the study. In one of the litters of the N group, only one animal was chosen, so that the experiment was standardized to the number of animals. After this step, the following groups were formed:

- Nourished (N) - maintained on a proteic diet until 60 days of age (n = 15);
- Undernourished (U) - maintained on a hypoproteic diet until 60 days of age (n = 15);
- Renourished (R) - formed by undernourished animals that were maintained on the hypoproteic diet until weaning after which they were maintained on the proteic diet until 60 days of age (n = 15).

Acquisition of systemic metabolic data

Group formation was followed by the experimental period (EP), during which the animals were divided in two types of monitoring protocols for the acquisition of metabolic parameters and the observance of differences between the monitoring models: 1) EP in the box (Bx): Five animals from each group (N, U, R) were individually maintained in standard rectangular cages with a protective aluminum top grill, until the 60th extrauterine day; 2) EP Metabolic (M): Ten animals from each group (N, U, R) were individually maintained in metabolic cages (TECNIPLAST®, model 3700M081, Buguggiate, Italy) where the following parameters were measured daily at the same time: body weight, water intake, feed intake, urine and feces excretion. A precision balance was used (Marte AS1000C, Sao Paulo, Brazil) to weigh the collectors and repositories of food and feces. The cages remained in a specific room where the daily entrance was restricted to two caretakers who were properly dressed to handle the animals.

On the 60th day, that corresponding to the pubertal stage of rats (VIAU et al., 2005), there were 15 animals in each group (10 metabolically monitored and 5 monitored in the boxes according to their diet) that were subjected to a final weighing and then euthanized.

Analysis of metabolic data

The adoption of this experimental methodology allowed for the acquisition of experimental data points, such as daily parameters...
or averages at the end of the experiment, mentioned above, as well as an analysis of the ratio between them. Thus, by analyzing the averages obtained throughout the EP, and combining two parameters, measurement can be done in percentages, the ratios of intake/body weight, feces/intake and urine/water consumption. The ratio of water/body weight was expressed by the unit ml/g.

For the purpose of daily acquisition of the common parameters, an investigation was conducted on the nutritional evolution of the animals on a temporal scale during the EP. Thus, the data used for effective comparisons and monitoring of the groups were combined after the 1st day into periods of four days (i.e., 2nd to 5th day, etc.).

Body weight development of animals in the N, U and R groups during the EP was obtained by the ratio between two weights established: weight number 1 was obtained when the animal (21 days postnatal) began the metabolic experiment; weight number 2 was obtained immediately before euthanasia (day 39 of the experiment).

Statistical analysis
The significance level was set at 95%. For simple comparisons (between groups, for example) Student's t test was used. For analyses comparing more than two factors (among three groups or parameters), we used the analysis of variance (ANOVA) with two factors, or with repeated measurements (for temporal analysis), in addition to Tukey's test to observe differences among the data.

RESULTS
Assessment of Monitoring
Using this experimental protocol with metabolic cage monitoring, no experimental obstacles were observed. Nevertheless, clinical differences were observed in animals from different groups. Surprisingly, mothers belonging to the U group gave birth to more puppies, which in turn had delayed fur development, compared with the animals in the N group. In the Metabolic EP, the animals showed variable behavior, sometimes active and reactive. At times, these animals displayed hypoactive, lethargic behavior, a characteristic present in all groups. On several occasions, the animals of the U group became enclosed in the feed storage container of the metabolic cage or, in the case of the animals monitored in the boxes, covered with wood shavings. Nevertheless, these animals had uniformly sparse fur, and were short and less healthy. These characteristics were not observed in the animals of the N group and, ultimately, in animals of the R group.

Some animals monitored in the metabolic cages, belonging to the U group, showed intense sweating, evidenced by the apparent transpiration on the lid of the cage. In addition, these animals were at least two times smaller in length compared with the other groups. The animals in the R group presented with pasty feces at the beginning of the feed re-adaptation and were slightly smaller than those in the N group.

Although there was a decrease, in both monitoring methods, of the body weight in the following order: N - R - U, when these values were compared within the groups monitored in the Bx and M methods, no statistically significant differences were observed (Table 1). The animals of the R group were the most approached to the animals in the N group, though there was a significant decrease in their body mass. However, a drastic decrease related to this parameter occurred in the animals of the U group.

Metabolic Assessment
The measurement of daily feed intake, water intake, feces and urine elimination allowed to obtain metabolic parameters between groups (Table 2). The data analysis showed similarities between groups R and N, except for the feed intake, which showed a slightly significant difference between the two groups. Nevertheless, the observed parameters
of animals in the U group remained well below those observed in the other groups.

*ANOVA; p<0.05

In the temporal analysis based on the EP, the body mass gain in the N group differed significantly from day to day, while the U group only obtained statistical difference from the 8th day. Animals in the R group also gained significant weight soon after the 2nd day of the experiment, and from the 4th day, this group showed a statistically significant difference compared with the animals in the U group (Figure 1, p<0.05).

Figure 1. Timeline analysis of male Wistar rat weight gain under three dietary regimes. Values are means ± SD. N = nourished; U = undernourished; R = renourished.

Food intake is significantly increased in the N animals starting from the 1st day of the experiment until the 10th day and, similarly, the R animals showed increased feed consumption from the 5th day until the 14th day, at which time both groups plateaued. The U showed significant feed intake from the 10th day until the 29th day, at which point there was a decrease in the intake. In the 1st day of monitoring, all groups are statistically equal (p>0.05). By the 2nd day, statistical differences for feed intake can already be observed between animals in the N and U groups, while animals in the R group only differ from U animals starting on the 17th day of the experiment (Figure 2 - A, p<0.05).

The N animals significantly increased their water intake daily from the 10th to the 25th day of monitoring and then plateaued. The animals of the R group significantly increased their water consumption from the 1st to the 22nd day of monitoring, and, similar to the N animals, then plateaued. Only after the 25th day of monitoring did the animals in the U group present a significant increase in water consumption. At first, the N and U animals did not differ in this parameter, and both were different from the R animals. However, by the 2nd day the R group did not differ from the N animals, and, after the 14th day, both the R and the N animals are statistically different from the U group (Figure 2 - B, p<0.05).

The temporal observation of fecal excretion showed that N animals differed from the U animals only after the 18th day of monitoring. From the 30th
day, all groups maintained statistically significant differences in a decreasing manner: N-R-U. Due to the technical limitations of the cage and/or due to soft feces of the animals, this assessment started from the 13th day of the experiment. Prior to that day there was not enough data for a statistical analysis (Figure 2 - C).

Animals in the N group showed a significant increase in urine excretion from the 14th day until the 26th day, at which point the difference was no longer significant. The U animals showed slightly significant urine excretion from the 25th to the 29th day, after which there was no significant difference. The R animals showed, from the beginning of the experiment, an increase in urine excretion (5th day) up to the 22nd day, at which point there was no longer any statistical significance. When comparing among the groups, the N animals excreted a statistically greater amount of urine than the U animals, while the R animals behaved similar to the U animals until the 13th day, at which point their urine excretion became significantly greater than the U animals (p<0.05). Animals in the R group excrete less urine than the N group until the 9th day; after which time there is no significant difference (Figure 2 - D, p>0.05).

Figure 2. Timeline graph of feed intake (A), water intake (B), fecal (C) and urine excretion (D) of male Wistar rats under three dietary regimes. Values are means ± SD. N = nourished; U = undernourished; R = renourished.

When assessing the ratios of food intake/body weight and water/body weight, it was observed that the animals in the U group had an elevated percentage, different from the other groups (N and R) that did not differ statistically. In descriptive terms, animals in the U group consumed daily 21 ± 4% of their weight in food and for each 1 g of their body weight these animals consumed the equivalent of 0.29 ± 0.04 ml of water daily. There was parity among the groups (N, U and R) in regards to the feces/intake ratio (%), while for the urine/water consumption ratio (%), the U group showed a slight decrease, approximately 7.5%, compared to the other groups, which was shown to be statistically significant (Table 3).

Table 3. Relationships among the metabolic means (± SD) of male Wistar rats under three dietary regimes.

*ANOVA; p<0.05
Animals of the R group differed from the other animals with regards to body mass progression. Thus, as observed in Figure 1, there was a multiplication of body weight in these animals, on the average of 9.1X, while in the animals of the N and U groups, this result was 4.7 and 2.4X, respectively. Thus, it was observed that animals of the R group grew, on average, 93.5% and 141% more than animals in the N and U, respectively. The order of growth among the groups was R>N>U (p<0.001 between the groups).

DISCUSSION

It is known that protein or protein-calorie undernourishment affects different organs and systems by either direct (cellularity and function) or indirect (growth and organism development) involvement, both in humans and in well-controlled experimental models (BAPTISTA JS et al., 2013; BEDI, 1991; GOMES et al., 2006; MONTE, 2000). Understanding the metabolism of animals subjected to malnutrition elucidates many aspects of this complex syndrome, helping scientists and health professionals with reliable data on the evolutionary, functional and morphological impairments, and on recovery from the disease. Therefore, an experimental model that can be subjected to severe protein undernourishment is useful since protein undernourishment is the main type of malnutrition in developing countries (loss of essential structural amino acids) and given the range of carbohydrate-rich foods(MONTE, 2000; MONTEIRO, 2003; NEUMANN; GEWA; BWIBO, 2004).

Several authors have worked with similar experimental protocols to the one used in the present study; however, they used 42 day-old animals(CASTELUCCI et al., 2002; GOMES et al., 2006; GREGGIO et al., 2010; LIBERTI et al., 2007; OLIVEIRA et al., 2010). Since there are no indications in these studies of animals being monitored in the period evaluated (60 days), nor of any metabolic monitoring.

The present study used metabolic monitoring, which allowed the collection of accurate data on the metabolism of the experimental animals, suggesting that the protocol is appropriate for the intended research. The first goal was to monitor possible behavioral or body changes between animals that are monitored differently: alone (metabolic) or collective (boxes). It was important because the first limitation of the study was to keep animals naturally living in community in seclusion and provide some bias for the research. The non-statistical differences in body weight shows that these animals did not suffer in seclusion and it did not become a bias(DOMÍNGUEZ-GERPE; REY-MÉNDEZ, 2000).

Low body weight and growth retardation are the primary reported data in undernourishment animals or humans (MUGERWA, 1971; NUNES et al., 2002; ROMANI; LIRA, 2004; WATERLOW, 1997); when the malnutrition is imposed on the mother this affects especially the intrauterine phase(BRETON et al., 2009; COUPÉ et al., 2009). This data is confirmed in the experimental model used, which showed that undernourished animals had the lowest body weight, in addition to the lowest intake of food and water, and the lowest excretion of urine and feces.

Although the weight increased in the R group animals, it was not sufficient to reach the level of the N group animals. In addition, the body length of the R animals did not approach those of the N animals, even with the long period of dietary change adopted (39 days). Similar findings were demonstrated in Wistar rats and in humans(CASTELUCCI et al., 2002; MONTE, 2000; NUNES et al., 2002). These observations have been attributed to changes in the cell proliferation of bone marrow precursors, which act in response to growth stimuli, causing a loss in development, precisely during the period in which the animal needs the most protein intake(NAKAJIMA et al., 2014).

In contrast, it was confirmed that undernourishment, based on the supply of the hypoproteic diet, led to disparate metabolic dysfunction in the animals of the U group, demonstrated by the excessive food intake that was disproportionate to their weight. This was an attempt to satiate their protein need, and the percentage of intake/body weight was on average 90% greater than that observed for the animals in the N and R groups. It is represents that Such results corroborate the work of Coupé and colleagues(COUPÉ et al., 2009), who showed that maternal nutrient restriction results in the appetite disturbance upon feeding recovery(DESAI; BABU; ROSS, 2007); however, metabolic data was not collected, so we cannot exactly compare results.

The metabolic imbalance triggers a massive release of endogenous corticosteroids via activation of the hypothalamic-pituitary-adrenal axis. This reaction originates from a hypothalamic stimulus of the adrenohypophysis, resulting in the release of adrenocorticotropic hormones that, in the adrenal cortex, will release corticosteroids(DOMÍNGUEZ-GERPE; REY-MÉNDEZ, 2000; NAKAJIMA et al., 2014). These corticosteroids stimulate the use of...
metabolic tools, such as lipolysis and proteolysis, in an attempt to return to homeostasis. They constitute one of the maintainers of the system, and are widely considered the cause of low birth weight and height observed in these animals. In addition, another three hormones are involved in this process: leptin, growth hormone and ghrelin. Leptin is produced and released in amounts directly proportional to the mass of adipose tissue in the body, signaling to the hypothalamus the amount of stored energy, as well as the regulation of food intake and thermogenesis (SAVINO et al., 2007). Protein restriction causes an increase in serum growth hormone performing lipolysis, providing organism maintenance through fatty acids, aided by corticosteroids, which change the peripheral energy source (PIMSTONE et al., 1968). Thus, leptin secretion decreases since there is less adipose tissue in these animals, decreasing the feedback process to the hypothalamus that limits the feeling of hunger, allowing excess food intake by the animal without the feeling of satiation.

Ghrelin, which is a protein produced in the gastrointestinal tract, is important in signaling and regulating the energy balance. This molecule triggers a signaling cascade that stimulates the release of gastric enzymes and growth hormones, in addition to increasing adiposity and energy consumption in animals and humans. Thus, it is believed that the observed increase in appetite in the animals in the present study is derived from the increase in ghrelin production, to the detriment of other proteins that reduce energy consumption, such as bombesin, cholecystokinin and glucagon-like peptide (WERNETTE; WHITE; ZIZZA, 2011).

Interestingly, all groups showed the same feces/intake ratio (%), which shows that there was no functional impairment of the gastrointestinal tract. These data were obtained through the morphoquantitative characterization of the myenteric plexus of undernourished rats (CASTELUCCI et al., 2002; GOMES et al., 2006; GREGGIO et al., 2010). Based on these studies and since the animals in the U group suffered protein deprivation, it is possible that the digestive system of these animals did not exhibit severe changes. Instead, the digestive system searches for ways to adapt to resist this injury and to absorb the maximum amount of nutrients: the data revealed that animals of the R group were similar, in regards to body weight, to the animals of the N group on the 2nd day of the experiment, while on the 4th day, their body mass gain was already significantly different from the body weight of the U group. Furthermore, it can be suggested that, based on the parameters of water consumption and urine excretion, there was no functional impairment of the excretory system since animals of the R group showed data equivalent to those seen for the animals in the N group on the 2nd and 6th days, respectively. Thus, it can be asserted that the R animals, in most parameters, behaved like the N animals, and they do not exhibit the same parameters as the U animals from the period between the 14th and 17th day of the EP, while the U animals maintain or decrease in their parameters.

Likewise, the metabolic disarray and consequent excessive release of endogenous corticosteroids (DOMÍNGUEZ-GERPE; REY-MÉNDEZ, 2000; NAKAJIMA et al., 2014) led to an 81% increase in the ratio of water intake/body weight of the U animals, while the urine excretion/water consumption ratio was 12% lower compared to the other two groups. This allows to infer that the imbalanced of metabolism leads to higher consumption and use of water to satisfy their metabolic needs. It is possible that this "cumulative" water is retained in the tissue, probably due to low levels of plasma proteins; however, no swelling was observed in these animals.

Except for the final body weight and the final average feed intake, all other analyzed parameters were similar between the animals of the R group and the animals of the N group, thus suggesting effective nutritional reestablishment.

In conclusion, it was observed that the protein undernourishment used in the present research model caused severe metabolic dysfunction showed by the imbalanced of Intake/body weight, Feces/intake, Water/body weight, Urine/water consumption. However, administration of a normal protein diet during an early period to animals previously undernourished proved to be effective, suggesting normalization of the parameters related to metabolism since these results were similar to those found in the control animals.

ACKNOWLEDGMENTS

We would like to thank Ms. Rosana Prisco for the statistical analyses. We regret to inform that our beloved colleague Silvia de Campos Boldrini tragically passed away in June 2011. Her charisma, belief in the goodness of people, determination for the enhancement of science and teaching of anatomy were the biggest legacy she has left in our lives. RESUMO: A subnutrição ainda é uma condição importante na saúde pública por afetar principalmente crianças. O presente estudo tem o objetivo de avaliar os efeitos da subnutrição pré-natal e renutrição pós-natal no metabolismo de ratos jovens. Quarenta e cinco ratos Wistar machos originados de diferentes ninhadas foram utilizados. O grupo Nutrido (N, n=15) e Subnutrido (U, n=30) foram mantidos sob dieta protéica e hipoprotéica (20% e 5% de caseína, respectivamente) desde a fase intrauterina até o final do experimento. O grupo Renutrido (R) contém 15 animais aleatoriamente selecionados do grupo U para consumir a dieta protéica a partir do dia 21 pós-natal (desmame). Todos os grupos foram mantidos até o dia 60. Os animais do grupo U desenvolveram atrasos na corporal e ingestão de alimento ficaram decrescentes na ordem N-R-U, enquanto que para todos os outros parâmetros não houve diferença estatística entre o animal N e R. Comparativamente ao grupo N e R, o grupo U consumiu 90% e 81% a mais de alimento e água, respectivamente. A subnutrição proteica induziu disfunção metabólica nos animais U. A semelhança nos parâmetros experimentais entre o grupo N e R sugere que a correção precoce da alimentação foi eficaz no retorno das funções orgânicas dos animais R.
