ABSTRACT: In pneumatic precision seeders, the regularity in seeds deposition is essential for a proper sowing process. Thus, the aim of this study was to verify the accuracy in the soybeans seed capturing in different vacuum pressures (3.5 kPa; 4.0 kPa; 5.0 kPa; 5.5 kPa and 6.0 kPa), the seed distribution in the seed lines as well as the fuel consumption in the tractor-seeder set. The experiment was carried out at the College of Agronomy – FCA/UNESP, Botucatu-SP. The outline was random blocks, in subplots layout banded of 30 × 3.15 m, with four replicates per treatment. A tractor-seeder set was used to collect the sample of fuel consumption and seed population. The real population of seed was collected in plastic bags fastened to the end of the conductor pipe, obtaining the population of the 5 central lines of the seeders. The acquisition of the fuel consumption data for each plot, was carried out using a flow meter. Thus, it was observed that the seeder distribution on the vacuum pressure at 3.5; 4.0 and 5.5 kPa decreased in the farthest lines when compared to the central lines. For the hourly fuel consumption, per area and also for the deposition of seeds the regularity in the distribution of seeds is affected when there is vacuum pressure below 5.0 kPa and, consequently, highest consumption. For soybean sowing, seeds having the characteristics described in this study, it is recommended to use vacuum pressure of 6.0 kPa. As a result, this vacuum pressure leads to the lowest fuel consumption per hour, 11.49 L h⁻¹ and worked area, 7.35 L ha⁻¹.

INTRODUCTION

The agricultural machinery and equipments, when are used properly, improves operational efficiency, allows the expansion of planted areas, provides increased yield and also allows complying the schedule of activities. However, such benefits may be annulled depending on the unsuitable use of the machines by the farmer.

For large extensions of crop area, it is essential the use of machines for depositing the seeds on the ground properly, providing an appropriate environment for the germination (KARAYEL; OZMERZI, 2007). Seed drill is defined by Machado et al. (2005), as being the agricultural machine that has the role to deposit all types of seeds on the ground, without mechanical damages, with recommended density, spacing and depth for the full development of the crop.

Sowing techniques and type of seeders play an important role in the deposition of seeds and seedling emergence which are directly associated to the plant growth and grain yield (KUMAR et al., 2013). Melo et al. (2013) evaluating precision seeders of horizontal and pneumatic disc, in two different operating speeds, concluded that the pneumatic seeder showed greater regularity in longitudinal seed distribution.

The seed metering mechanism in the pneumatic seeders has its own particular characteristics, such as peripheral speed of the disc and pressure of vacuum (ALONÇO et al., 2014). The pneumatic seed metering mechanism can provide a better distribution of seeds (TOURINO et al., 2009), less damage, better adjustment and better accuracy (ZHAN et al., 2010).

Li et al. (2012) highlighted the flexibility of the use with different types and sizes of seeds, with more precise dosing rates, less damage to the seed, better control and adaptation and a larger application spectrum. Oliveira et al. (2009), Jasper et al. (2011) and Melo et al. (2013) also identified best performance of these pneumatic seed metering mechanism in relation to mechanic metering.

The speed of displacement of the tractor-seeder set is an important factor in the sowing operation (SILVEIRA et al., 2013). However, other factors can interfere in the accuracy of the sowing, Reis and Forcellini (2002) cite the regularity of distribution of seeds and seed metering errors. The accuracy of sowing depends directly on the accuracy in the seed metering mechanism performed...
Seeder performance under different pressures…

by the meter of seed that, according to Dias (2009), is the most important organ of the seeder.

On the pneumatic meter, the selector position in the disc of seeds is another important item to the proper sowing, being the vacuum pressure of the meters the one that leads to suitable densities for each crops. The majority of studies with seeders equipped with these types of mechanisms focus on the speed of displacement, as in the works of Liu et al. (2004), Celik et al. (2007), Dias et al. (2009) and Jasper et al. (2011).

Thus, the aim of this study was to verify the accuracy of the soybean seed capturing, in the vacuum pressures 3.5 kPa; 4.0 kPa; 5.0 kPa; 5.5 kPa and 6.0 kPa, the distribution of seeds by sowing lines and fuel consumption in a tractor-seeder set.

MATERIAL AND METHODS

The experiment was carried out in 2015, at the College of Agronomy - FCA / UNESP, located in Botucatu-SP (22°51’S and 48°26’W, average altitude of 770 meters).

The experimental outline was composed by blocks at random in subplots layout banded with four replications per treatment. The treatments are composed by the evaluation of accuracy of the seed capturing according to the selector positions in the seed metering device, represented by -5, -3, 0, 3 and 5, which are equivalent to the vacuum pressures represented by 3.5 kPa; 4.0 kPa; 5.0 kPa; 5.5 kPa and 6.0 kPa and distribution of seeds for sowing line (L1: line 1; L2: line 2; L3: line 3; L4: line 4 and L5: line 5). The variables seed population and fuel consumption were analyzed. The experimental area was 30 m x 3.15 (94.5 m²) for each treatment.

A tractor-seeder set was carrying out the experiment, with New Holland tires, model TS 110, 4x2 FWA (front wheel assist), with engine rated power of 80.5 kW (109.5 hp), and a seeder precision Jumil, model Exacta 2980 PD, with seven seeding lines, helicoidal fertilizer, and pneumatic system for seeding deposition, with seed discs Jumil 7045 (diameter 247mm, thickness 1mm, number of holes 75, hole diameter 5mm, 4.5mm distance between holes), spaced at 0.45 m, totaling 2.25m wide.

The soybean seeds were characterized by the weight of a thousand seeds and sphericity, that it was determined by the equation described by Karayel et al. (2004):

$$\phi = \frac{(L \cdot W \cdot T)^{1/3}}{L} \times 100$$

Where: $\phi$ is the sphericity (%); L, W and T refers to the length, width and thickness of the seed (mm), respectively.

The soybean seed dimensions were determined with the aid of a pachymeter with accuracy of 0.05 mm, in 50 seeds, with length of 6.7 mm, width of 5.8 mm, thickness of 5.5 mm, sphericity of 89.1 mm and weight of 159 g for thousand seeds. EMBRAPA (1991) describes that one of the factors which affects the distribution of the seeds is the uniformity of seed width.

The tractor-seeder set was driven at 5 km h⁻¹, with an approximate rotation in a 1900 rpm engine, without front wheel assist, on solid ground with steepness lower than 5%, with a theoretical population of 266,600 seeds ha⁻¹ (12 seeds m⁻²).

The real population of seeds was collected in plastic bags fastened to the end of the conductor pipe, obtaining the populations of the 5 central lines of the seeder, and after this procedure the number of the seeds were measured by hand, adjusting the number to seeds per hectare.

The acquisition of fuel consumption data for each plot was carried out using a flow meter "oval Flowmate” Oval M-III model, accurate to 0.01 mL. The flow meter was installed close to the tractor fuel filter, registering one pulse unit for each ml of fuel which passes by it.

The hourly fuel consumption and fuel consumption by worked area the following were calculated by the ensuing formulas:

$$C_h = 3.6 \times \frac{C_c}{T_p}$$

Where: $C_h$ is hourly fuel consumption L h⁻¹; $C_c$ is fuel consumption per plot; $T_p$ is time spent per plot; 3.6 is a correction factor.

$$C_{ha} = \frac{C_h \cdot T}{h_a}$$

Where: $C_{ha}$ is fuel consumption by worked area L ha⁻¹; $C_h$ is fuel hourly consumption L h⁻¹; $T$ is time spent per hectare.

The results were submitted to analysis of variance at 5% probability by the F test, the means were compared by Tukey test at 5% significance, with the statistical program SISVAR (Ferreira, 2011). After analysis of variance quantitative treatments were submitted to regression analysis, with the statistical program SigmaPlot 11.0.

RESULTS AND DISCUSSION

The soybean plantability is affected when the vacuum pressure is below 5.0 kPa, for the hourly fuel consumption, worked area and seed deposition it is verified that, as shown in Table 1.

Sowing with adjustment of the vacuum pressure 6.0 kPa in the seed metering device, were deposited more adequately population, it is observed the statistical similarity with pressures of 5.5 and 5.0 kPa. For the fuel consumption has the lowest consumptions to 5.5 and 6.0 kPa vacuum pressure.

In a seeder the selector position and the seed metering device allows only one adjustment of vacuum pressure, with the adaptation of suction to the seed weight (JUMIL, 2010). From this information is appropriate, based on the data of Table 1, to choice the selector position in 3 or 5, which corresponds in 5.5 and 6.0 kPa.

Francetto et al. (2015) describe that the sizing of the seeder can decrease the production cost due to the reduced number of interruptions for fuel supply and Machado et al. (2015) evaluating variable rate in seeders described that the causes of poor performance is attributed to effects such as equipment calibration.

The distribution of seeds per set was also covered in this study, with the seeds being collected in 5 lines of the seeder. The results are shown as polynomial regression in Figure 1.

Based on the regression analysis, it is possible to conclude that the seed distribution in the vacuum pressures 3.5; 4.0 and 5.5 kPa (Figure 1 A, B and D) decrease the farthest lines when related to the center line of the seeder, which is where the engine responsible by the vacuum is located. However, in the pressure 5.5 kPa there is a significant quadratic effect, but with less accuracy for lines 1 and 5 due to the standard error, which makes it similar to 5.0 and 6.0 kPa pressure. As already described in Table 1, the highest vacuum pressures lead to better distribution of soybean seeds.

Tourino et al. (2007) reported that in the seed metering pneumatic the negative pressure can influence in the capturing of the seeds. To define the variation in the distribution of seeds (Table 2) as acceptable < 10% or not > 10% among the lines of the same seeder, the methodology proposed by Weirich Neto et al. (2015) was adopted, calculating by the percentage among the number of seeds by lines, was obtained through the difference between the highest and lowest number of seeds divided by the lowest number of seeds.

Pointing out the data previously indicated in this study, there was lowest variations for the largest vacuum pressures. Considering the average population of 233,902 seeds ha^{-1} and variation of 0.21%, these are the data that come closest to the intended for sowing, highlighting the vacuum pressure 6.0 kPa. Schimandeiro et al. (2006) also found variations among the sowing lines, with larger populations to the center lines. Weirich Neto et al. (2015) evaluating 64 seeders in five crops, point out the variation over 10% among the lines of the same seeder, which could bring loss to the productivity.

CONCLUSIONS

The vacuum pressure of 6.0 kPa is recommended for soybean sowing, when the seeds have sphericity of 89.1 mm and weight of thousand seeds of 159 g. As a result, this vacuum pressure leads to the lowest fuel consumption per hour, 11.49 L h⁻¹ and worked area, 7.35 L ha⁻¹.

The adjustment and inspection line by line of the seeder it is essential for less variation among the sowing lines, thus achieving better results. For seeds of lower weight it is required higher vacuum pressure.

RESUMO: Nas semeadoras de precisão pneumáticas a regularidade na deposição de sementes é primordial para uma correta semeadura. Assim, o objetivo deste estudo foi verificar a acurácia na captura de sementes de soja em diferentes pressões de vácuo (3,5 kPa; 4 kPa; 5 kPa; 5,5 kPa e 6 kPa), a distribuição das sementes nas linhas da semeadora e, também, verificar o consumo de combustível do conjunto trator-semeadora. Realizou-se o experimento na Faculdade de Ciências Agronômicas – FCA/UNESP, Botucatu-SP. O delineamento experimental foi de blocos ao acaso, em esquema de subdivisões (faixas de 30 × 3,15 m), com quatro repetições por tratamento. Um conjunto trator-semeadora foi utilizado coletando-se as amostras de consumo de combustível e população de sementes. Sendo as sementes coletadas em sacos plásticos fixados ao final do tubo condutor, obtendo as populações das 5 linhas centrais da semeadora. A obtenção dos dados de consumo de combustível para cada parcela foi realizada utilizando-se um fluxômetro. Assim verificou-se que a distribuição de sementes nas pressões de vácuo 3,5; 4 e 5,5 kPa decrescem nas linhas mais distantes do centro da semeadora. Para o consumo de combustível horário, por área e deposição de sementes verifica-se que a regularidade na distribuição de sementes é afetada quando se tem pressões de vácuo abaixo de 5 kPa e, consequentemente, maiores consumos. Para semeadura de soja, com as características das sementes como neste trabalho, é recomendando utilizar a pressão de vácuo de 6 kPa. Apresentando esta pressão de vácuo menor consumo de combustível por hora, 11,49 L h⁻¹ e área trabalhada, 7,35 L ha⁻¹.
